A dynamical model to predict the Covid-19 in Spain

The model used to predict the Covid-19 evolution in Spain is based on the classical Kermack-Mackendrick models. These models provide a coupled system of three differential equations for the main variables of an epidemic: susceptible, infected and recovered populations.

The model here proposed generalises these models by including continuum delays as integral equations in some model parts, in order to consider the evolution delay of some model variables. Thus, the model becomes a coupled system of integro-differential equations.

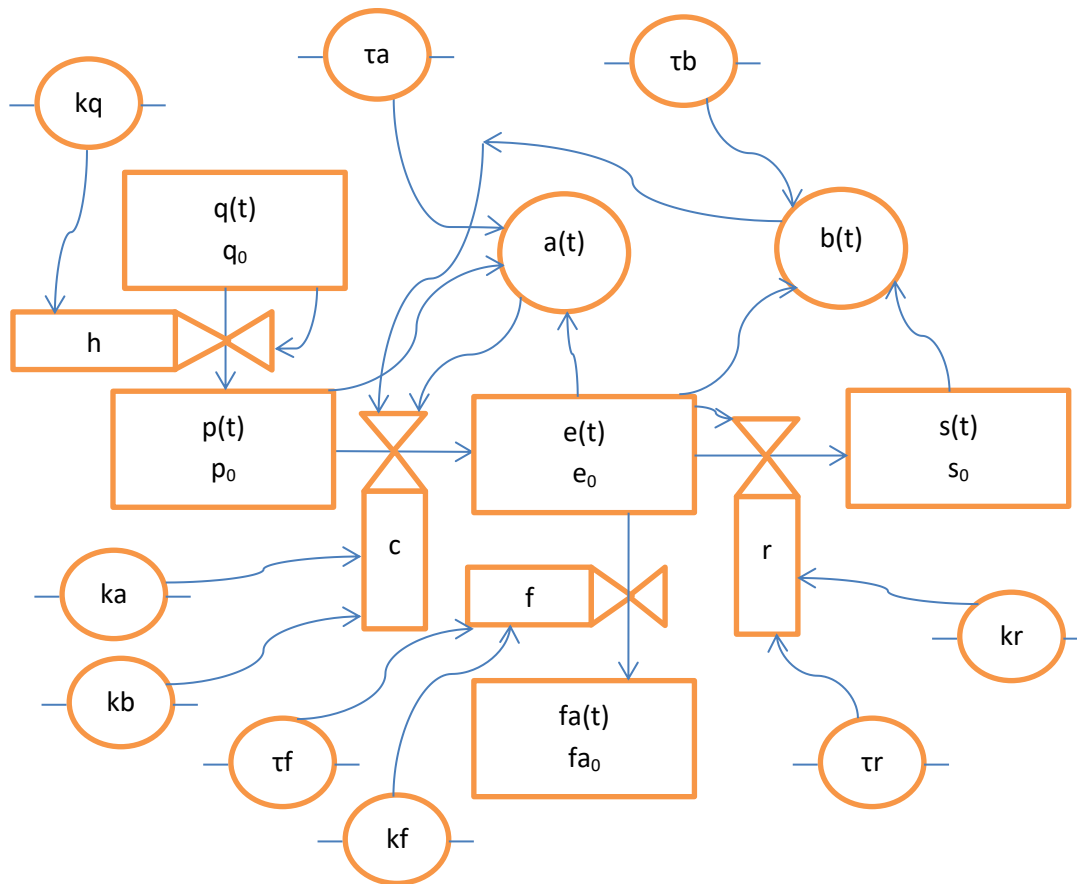

In addition, the Jay W. Forrester methodology, developed in the MIT and generalised in the “Escola d’Investigació Operativa i Sistemes de la ciutat de València” is used. This methodology uses a universal language, represented by the hydrodynamic diagram (Section 1), to build dynamical models of complex systems.

The model presented has input variables or parameters (whose values must be provided) and output variables (Section 2) computed by the system of integro-differential equations (Section 3). To get the parameter values for Spain the model is calibrated by using the experimental data provided by the Spanish Health Ministry (Section 4). We also provide a day to day model update, predicting the infected population values: at short time term for the next three days, and at long time term computing the day and the value of the maximum infected population (Section 5). For any other information, please contact the authors through their electronic mails.

5. Short and long time term prediction.
6. Comments.

1. Hydrodynamic Diagram

2. Model variables

2.1. Input variables or parameters:

kq: susceptibility rate

τ_a : continuum susceptible-infected populations interaction delay

tb: continuum susceptible-recovered populations interaction delay

ka: susceptible-infected populations interaction rate

kb: susceptible-recovered populations interaction rate

τ_f : continuum infected population deaths delay

kf: infected population deaths rate

| tr: | continuum recovered population delay |

kr: recovering population rate

2.2. Output variables (with equation):

$q(t)$: country population (Spain)

$h(t)$: susceptible population flow

$p(t)$: susceptible population

$c(t)$: infection flow
 $e(t)$: infected population
 $f(t)$: deaths flow
 $fa(t)$: cumulated deaths
 $r(t)$: recovered population flow
 $s(t)$: cumulated recovered population

3. Model equations

$$\frac{dq(t)}{dt} = -h(t)$$

$$h(t) = kq \cdot q(t)$$

$$\frac{dp(t)}{dt} = h(t) - c(t)$$

$$c(t) = ka \cdot a(t) + kb \cdot b(t)$$

$$a(t) = \int_{t_0}^t E^{\frac{x-t}{\tau a}} p(x) e(x) dx$$

$$b(t) = \int_{t_0}^t E^{\frac{x-t}{\tau b}} p(x) s(x) dx$$

$$\frac{de(t)}{dt} = c(t) - f(t) - r(t)$$

$$f(t) = kf \int_{t_0}^t E^{\frac{x-t}{\tau f}} e(x) dx$$

$$r(t) = kr \int_{t_0}^t E^{\frac{x-t}{\tau r}} e(x) dx$$

$$\frac{ds(t)}{dt} = r(t)$$

Remark: the red equations have been included due to, in some pandemics or epidemics, the interaction between infected and recovered populations can influence in the infected population increase. However, this red colour points out that this influence does not reproduce the correct results in the present model. Therefore, mathematically, just taking the parameter kb value as $kb=0$ avoids the presence of this term interaction in the computations.

4. Model calibration

The model is calibrated by using the experimental data corresponding to the $c(t)$, $e(t)$, $fa(t)$ and $s(t)$ variables. They are provided day to day by the Spanish Health Ministry, which can be found in the link:

“<https://www.mscbs.gob.es/profesionales/saludPublica/ccayes/alertasActual/nCov-China/situacionActual.htm>”

The model calibration is made by the random number generation method for the parameter values.

First of all, the comparison between the experimental data of the infected population and the theoretical values corresponding to the calibrated model is presented. The comparison for today is presented in Figure 1:

Figure 1: Infected population (dots) and the predicted infected population by the calibrated model (curve) versus time in days (the zero day is 2020 January 31). Determination Coefficient $R^2=0.997$.

Remark: The determination coefficient varies between 0 and 1. The closer the unit the better the model fits the considered reality.

5. Short and long time term prediction

The prediction objective at short time term is to provide the infected population estimation for the next three days, that is:

Day 26/03/2020: 58684 infected

Day 27/03/2020: 69053 infected

Day 28/03/2020: 80508 infected

The prediction objective at long time term is to find the infected population peak: the day which the infected population starts to decrease from. See Figure 2, which provides a prediction for 80 days, starting from January 31:

Figure 2: Infected population prediction (curve) versus time in days (the zero day is 2020 January 31).

Figure 2 provides the infected population peak, which would happen in **April 6** as a maximum of **165395 infected people**.

6. Comments

Take into account that the model just provides estimations but not exact values, for both short and long time term predictions. In addition, these predictions can change by considering the incorporation of new data in the model calibration.

The model can be improved by:

- (a) Formulating it as a stochastic model, that is, by providing every day predictions with confidence intervals. This improvement would afford more reliability to the model.
- (b) Calibrating the model by using a genetic algorithm instead a simple random number generation. This method would provide a better fitting between the model results and the experimental data and, as a consequence, better predictions.
- (c) Introducing the political decisions as influences on the parameters. Thus, the model could be a ruling tool for future similar crises.

These improvements will be tried in the collaboration with more scientists, taking into account the present restrictions due to the crisis. For similar comparable approaches see also the following links:
